

Discussion Question

How clinically meaningful is event-free survival as a primary endpoint for patients with BCG-unresponsive NMIBC? In comparison to progression-free survival?

- Event-free survival typically is defined as the time from randomization until **recurrence** of high-risk disease or progression or death
- Progression is usually defined as an increase in stage (T, N, or M stage) or grade

Is complete response rate, as we have seen in many BCG-Unresponsive CIS single-arm trials, a meaningful endpoint? Or would recurrence-free survival be more meaningful?

Delaying cystectomy runs the risk of missing a window of opportunity. Quality of life differences after cystectomy are difficult to demonstrate. What is the value of assessing cystectomy-free survival rigorously as a secondary endpoint?
